1 Question 1

To generate an exponential random variable from the uniform distribution, all we have to do is:

- 1. Generate a random number in [0, 1] from an uniform distribution. This can be done by calling the rand() function built into C++.
- 2. Return $X = F^{-1}(U)$, where F^{-1} is the inverse of the exponential distribution function. This is derived below.

$$y = 1 - e^{-\lambda x}$$

$$x = 1 - e^{-\lambda y}$$

$$1 - x = e^{-\lambda y}$$

$$F^{-1} = -\frac{\ln(1 - x)}{\lambda}$$

The implementation for the method that generates exponentially distributed random numbers expDistr can be found in utils.cc.

The implementation for the C++ code generates 1000 exponential random variables with $\lambda=75$ is in main.cc and is named validExpDistr and is run as a sanity check before the simulation. From our experiment, the mean is 0.0129 and variance is 0.000166. The theoretical values for the mean and variance are $\mu=\frac{1}{\lambda}=\frac{1}{75}\approx 0.013$ and $\sigma=\frac{1}{\lambda^2}=\frac{1}{5625}\approx 0.00017$. Our experimental values are within 1% of the expected values. Thus, we verify our generator is valid.

SHOW CODE?

2 Question 2

I decided to build the M/M/1/K queue first and let the M/M/1 queue be a special case of it where $K=\infty$. In my implementation, I decoupled the *simulation* from the *queue* itself.

In simulation.cc, I wrote a method simulateMM1Queue(double alpha, doubled L, double lambda, double C, double T), where these variables follow the definition stated in the lab outline. This method generates the observer event times and packet arrival times via a Poission distribution method genPoissionDistr (which repeatedly calls our exponential random number generator for intervals between events). The packet sizes were generated using the exponential random number generator. To get the packet departure time for packet p, simply calculate $\frac{L_p}{C}$ +max(lastPacketDepartureTime, packetArrivalTime). We combine these events into a vector of Events and then sort time by their event time. We then iterate through the events and feed them to the queue. At the end, we inspect the counters for the queue and calculate our performance metrics.

In queue.cc, we initialize our counters and expose a method handle (Event e) which consumes an event and adjusts the state of counters to reflect the event. Specifically, we have counters for numIdle to reflect the number of observations in which the queue was idle, numObservations for the total number of observations, numArrival to count the number of packets that arrived at the queue, numDepartures for the number of packets that departed the queue (sent off by the server), and an accumulator sumSampledQueueSize which accumulates the size of the queue every time we observer it. Depending on the type of the event (specified by an enum), we do several different things:

- OBSERVER: increment numObservations, increment numIdle if the queue is idle (currentSize = numArrivals numDepartures), and add the current size of the queue to a sum to calculate the average size later on.
- ARRIVAL: increment numArrivals.
- DEPARTURE: increment numDepartures.

You may have noticed that this method also generates an event. This is for the $\rm M/M/1/K$ queue case, where dynamic events are generated on the fly. In particular, departure events may be generated on packet arrival. We will discuss this later on.

The core of the implementation is made available in the Appendix. For implementation of lower level functions, such as the random number generator, please refer to the source code submitted with the lab.

3 Question 3

Setting $L=12000,~C=10^6,~T=10,~\alpha=100,$ we must determine λ as a function of ρ , where $0.25<\rho<0.95.$ This is an easy arrangement $\lambda=\frac{\rho C}{L}.$ We then create a for loop from the lower and upper bounds of ρ and determine the necessary parameters for the simulation. We record the results below.

ρ	E[N]	P_{IDLE}
0.26	0.314	0.740
0.36	0.540	0.626
0.46	1.57	0.470
0.56	1.41	0.390
0.66	1.56	0.397
0.76	4.18	0.209
0.86	5.69	0.207

1. E[N]: To calculate this value, every time the queue processes an OBSERVER event, we add the currentSize = numArrivals - numDepartures to an accumulator. At the end of the simulation, we find that $E[N] = \frac{accumulator}{numObservations}$. The results are given below.

Average Q Size vs Utilization (MM1)

2. P_{IDLE} : To calculate this value, every time the queue processes an OBSERVER

event, we increment our idle counter like so numIdle+ = (currentSize) == 0). Then at the end of the simulation $P_{IDLE} = \frac{\text{numIdle}}{\text{numObservations}}$.

utilization

4 Question 4

For $\rho=1.2$, we observe that $E[n]\approx 55$, which is a sharp increase from the values above. At the same time, $P_{IDLE}\approx 0$, which is close to the previous values. The reason for this change is because of the increase in average queuing delay. As (average) queue utilization increases past 1, we see that more data arrives $(L\lambda)$ then the server can output (C), on average. This means that there is an increased likelihood that an incoming packet will be waiting in the queue. This increase in average queuing delay is reflected in the fact that the average queue size is now sharply greater than before. Note that the proportion idle of the queue did not change significantly as for $\rho\approx 1$, the queue is already being heavily utilized and so the proportion of time it is idle is already pretty low. Increasing ρ any further will not change this metric by too much.

5 Question 5

As mentioned previously, M/M/1 is just a special case of M/M/1/K. Thus, our implementation strategy for the queue did not change, although now we execute

a different portion of the queue code.

In simulation.cc we implement the method simulateMM1KQueue(double alpha, double L, double lambda, double C, double T, int K). These parameter are synonymous in meaning to those defined in the lab outline. Note that we define a new parameter K, which now indicates the max size of the queue. Like previously, we use genPoissionDistr to generate the observer event times and packet arrival times, however the difference this time is that we no longer geneerate the departure times and packet sizes. We fuse those two events into a single event queue using a 2 pointer approach. Then, we create a new queue called dynamicEvents which is responsible for storing events generated on the fly (i.e. departure events). We use another queue for departure events instead of inserting into one event queue because we would have to binary search for proper index, which is computationally more expensive than having two queues. Every time we consume an event, all we have to do is compare the front of the two queues events and dyanmicEvents to choose the earliest one, and wll we have to do to insert a new event is to push it back to the end of the dynamicEvents queue because packets arriving later will depart later due to the FIFO property. We then feed events from these two queues into the network queue and computer our performance metrics at the end.

There is no new code in queue.cc. However, for the M/M/1/K we do use two additional counters - numDropped to record the number of packets dropped and numPacketsGenerated to keep track of the total number of packets generated. We set in the queue constructor the isGenDepartureEvents flag to allow it to generate departure events, pass linkCapacity so that we can compute service time on the fly, and input the maxSize of the queue. On ARRIVAL events, we now check if the queue is at max capacity and drop the packet and increment the dropped counter if it is. We also generate a new departure event for packets that aren't dropped via the same method as previously (using the last departure time and the service time). This departure event is added to the dynamicEvents queue and automatically consumed by the network queue later on.

6 Question 6

Setting $L=12000,~C=10^6,~T=10,~\alpha=100,$ we must determine λ as a function of ρ using the same method previously.

1. E[N]: To calculate this value, every time the queue processes an OBSERVER event, we add the currentSize = numArrivals - numDepartures to an accumulator. At the end of the simulation, we find that $E[N] = \frac{accumulator}{numObservations}$. The results are given below.

ρ	K = 1	K = 10	K = 40	$K = \inf$
0.6	1.13078	1.11565	1.19658	1.44925
0.7	1.47799	1.93219	2.87003	1.77495
0.8	2.03437	2.77208	3.94422	2.29563
0.9	2.4027	3.86413	7.33369	4.93624
1	2.5391	4.67211	19.9806	50.2159
1.1	2.99901	5.55578	8.31594	48.0913
1.2	3.05712	6.94859	34.399	110.481
1.3	3.31509	7.50448	32.6788	120.194
1.4	3.359	7.55765	36.1759	129.229

Avg Q Size vs Utilization (MM1K)

2. P_{LOSS} : To calculate this value, we simply look at $P_{LOSS} = \frac{numDropped}{numGenerated}$.
